**Key Words:** Congenital melanocytic nevi

**Abstract**

**Observation:** Congenital melanocytic nevi (CMN) are pigmented lesions appearing at birth or after few days of birth. We present an outstanding case of giant CMN in woman located on the back.

**Introduction**

Congenital melanocytic nevi (CMN) are pigmented lesions appearing at birth or after few days of birth. CMN are classified as giant when the surface diameter is ≥ 20 cm [1]. Giant CMN are less frequent than small nevi, but show a significant higher risk of developing melanoma and neurocutaneous melanocytosis [2, 3]. We present an outstanding case of giant CMN in woman located on the back.

**Case Report**

A 47-year-old woman presented with a pigmented plaque on her back, which was present since birth and had gradually increased to the present size. This condition had a psychological and social impact in our patient during her childhood, since she tended to avoid situations in which she had to undress, such as swimming and sports. However parents declined excisions. At age of 47, she was referred to our department of dermatology for assessment. The growth of the nevus discontinued at age of 20 and since then no other changes in shape, color or thickening were observed. Clinical examination revealed a huge (43 x 38 cm), hairy, brown-black congenital melanocytic nevus involving the neck and the upper back (Figure 1). Magnetic resonance imaging of the brain was negative for melanosis and thickening of leptomeninges. Findings on the dermatoscopy revealed areas with globular and homogeneous pattern, brown and black dots and globules, small milia-like cysts and terminal hairs. After considering the

benign clinical and dermatoscopic outcomes and the risk of inaesthetic result with the surgical re-
move of this large lesion, a conservative approach was decided.

Discussion

Giant CNM occur in approximately 1 of 20,000 newborns in Caucasion population [4]. The etiology of CNM is caused by a morphogenic error in the neuroectoderm leading to a dysregulated growth of melanoblasts during the 5th and 24th weeks of ges-
tation [5]. The importance of CNM lies in the fact that these lesions may be precursors of malignant melanoma, particulary those large lesions (≥ 20 cm) which shows a lifetime risk of melanoma between 4.5% and 10% [6]. Early evaluation and surgical remo-
vals of large CNM are indicated not only because of the high potential of degeneration to a melanoma, but also due to the aesthetic impact of these conditions. However, the management should be individualized in each patient considering the location and size of the nevus, the psychosocial impact, the risk of surgery and the cosmetic issues related to the surgical scar. In our patient, although the psychosocial impact of giant nevi was considerable, the lack of dermatoscopic ma-
lignant signs as well as the cosmetic issues related of the huge size of the lesion resulted in a conservative management.

When removal of giant atypical CNM is deci-
ded, it should be performed in early stages to avoid large and excessive scar: the surgical challenge is the functional and aesthetic re-
construction. A staged excision and use of tis-
sue-expander or an intermeadiate-thickness skin graft are usually required in giant CNM.

In our patient, serial examination with der-
matoscopy are performed periodically with no signs of malignant transformation during the follow-up.
